

this material were carried out in 1958, the results of which may be summarized as follows:

(a) T2-10a \underline{R}^r and T4-10b \underline{R}^r are, in fact, significantly stronger in aleurone pigment-producing action than standard \underline{R}^r in a normal chromosome 10.

(b) On reincorporation into a normal chromosome 10 from a T chromosome, \underline{R}^r retains its enhanced pigment-producing action. This observation excludes an explanation of the phenomenon in terms of position effect of the conventional kind.

(c) Enhancement of \underline{R}^r action does not appear in the offspring of plants carrying a T chromosome bearing an \underline{r} (colorless aleurone) allele, with standard \underline{R}^r present in a normal chromosome 10 ($\underline{Tr}/\underline{R}^r$). Evidently the original change to enhanced \underline{R}^r action requires that \underline{R}^r be in coupling, not in repulsion, with T, in the translocation heterozygote.

(d) Testcrosses on \underline{rr} plants of $\underline{TR}^r/\underline{TR}^r$ homozygotes yield the same enhanced \underline{R}^r phenotype as results when pollen from $\underline{TR}^r/\underline{r}$ plants is used. Seemingly, "pairing stress" at meiosis is not a factor in the enhancement process.

(e) Partial reversion of the enhanced pigment-producing action of \underline{R}^r in a \underline{TR}^r chromosome toward the level of standard \underline{R}^r is found among the offspring of $\underline{TR}^r/\underline{R}^r$ plants.

(f) Paramutability of \underline{TR}^r in $\underline{TR}^r/\underline{R}^r$ heterozygotes (and also of \underline{R}^r extracted from a \underline{TR}^r chromosome) is markedly lower than that of standard \underline{R}^r in ordinary $\underline{R}^r/\underline{R}^r$ individuals.

(g) The partial reversion of enhanced \underline{R}^r toward standard \underline{R}^r , observed among the offspring of $\underline{TR}^r/\underline{R}^r$ plants, is paralleled by an increase in paramutability when an \underline{R}^r allele with this history is made heterozygous with stippled.

3. Basis of the light stippled phenotype.

A few stippled aleurone kernels with a much reduced frequency of spotting were regularly observed in a series of matings of $\underline{R}^r/\underline{R}^r$ and $\underline{R}^r/\underline{r}$ with \underline{rgrg} . When such kernels were planted, and the resulting individuals were selfed, ears were formed that showed an \underline{R}^r (light) phenotype. The frequency of such germinal changes to \underline{R}^r (light) was found to be 58.7/1000 and 50.3/1000 \underline{R}^r gametes when tested in $\underline{R}^r/\underline{R}^r$ and $\underline{R}^r/\underline{r}$ heterozygotes, respectively. A population of 13,084 \underline{R}^r

gametes was tested. The frequency of germinal changes to \underline{R}^{st} (light) in homozygous \underline{R}^{st} stocks was found to be only 0.3/1000, based on a population of 18,586 \underline{R}^{st} gametes.

The difference between the frequency of changes to \underline{R}^{st} (light) in \underline{R}^{st} heterozygotes with \underline{R}^R and \underline{r}^r and in \underline{R}^{st} homozygotes suggested that such changes are either 1) associated with heterozygosity, per se, at the \underline{R} locus, or 2) a product of crossing over between \underline{R}^{st} and a linked modifier carried on the \underline{R}^R and \underline{r}^r chromosomes.

A test was made using a proximal marker, golden (\underline{g}), and a distal marker, a terminal heterochromatic knob (\underline{K}), to test for the association of crossing over with changes of \underline{R}^{st} to \underline{R}^{st} (light). The following cross was made: $\underline{g} \underline{R}^G \underline{K}/\underline{G} \underline{R}^{st} \underline{k} \times \underline{g} \underline{r} \underline{k}$. \underline{R}^{st} (light) kernels were selected and planted; the resulting plants were scored for golden, and the ears were pollinated with \underline{r}^r . \underline{K} was scored by making counts of the number of \underline{R}^{st} (light) and \underline{r} kernels on each ear to determine whether preferential segregation for \underline{R}^{st} (light) had occurred. The results from this test showed that changes to \underline{R}^{st} (light) were always associated with crossing over between \underline{R} and \underline{K} .

It is hypothesized that there is a locus about 5.7 crossover units distal to \underline{R} , the alleles of which modify the expression of \underline{R}^{st} . The modifier conditioning normal stippled expression was designated \underline{M}^{st} , and the one conditioning \underline{R}^{st} (light) expression was designated \underline{m}^{st} .

The \underline{R}^R and \underline{r}^r chromosomes in the first test carried \underline{m}^{st} , and the crosses made may now be diagrammed as follows: $\underline{R}^R \underline{m}^{st}/\underline{r}^r \underline{M}^{st} \times \underline{r}^r \underline{m}^{st}$. Crossing over produced an $\underline{R}^{st} \underline{m}^{st}$ chromosome which conditions \underline{R}^{st} (light). The complementary crossover class would be $\underline{R}^R \underline{M}^{st}$ in the $\underline{R}^R \underline{R}^{st}$ heterozygotes, and $\underline{r}^r \underline{M}^{st}$ in the $\underline{R}^{st} \underline{r}^r$ heterozygotes. Both of these complementary crossover classes have been identified, and they occur with the same frequency as \underline{R}^{st} (light).

The changes of \underline{R}^{st} to \underline{R}^{st} (light) in \underline{R}^{st} homozygotes cannot be ascribed to recombination between \underline{R}^{st} and a linked modifier. The few mutants obtained from these matings have been interpreted as mutations of \underline{M}^{st} to \underline{m}^{st} or transpositions of \underline{M}^{st} (see below).

R. B. Ashman

4. Transposability of \underline{M}^{st} , a modifier of stippled aleurone.

Numerous self-colored kernels were selected after the following cross: $\underline{R}^{st} \underline{r}^r \underline{g} \times \underline{r}^r \underline{R}^G \underline{g}$. These kernels were grown out to verify the presumed mutations of \underline{R}^{st} to self-color. The ears produced by the resulting plants were pollinated with $\underline{r}^r \underline{r}^r$. As observed in an earlier test, less than half of the phenotypically self-colored kernels gave self-colored (\underline{R}^{sc}) offspring. Fifty plants, in fact, grown from 64 self-colored kernels did not
